Abstract

Paratuberculosis, caused by *Mycobacterium avium* subsp. *paratuberculosis* (MAP), remains a persistent One Health concern due to its slow clinical course, environmental resilience, wide circulation in ruminant systems, and unresolved zoonotic implications. To characterise MAP exposure across Türkiye's goat populations, we conducted a nationwide genomic survey encompassing seven breeds from 36 farms in 11 provinces. High-density SNP genotyping combined with mutual-information–based feature preselection retained informative, non-redundant loci capturing both linear and nonlinear components of disease architecture.

Nine complementary machine-learning models were applied to identify host genetic factors underlying MAP infection, and an ensemble importance framework resolved 31 FDR-controlled SNPs consistently associated with MAP status. Functional annotation implicated immune processes including cytokine–receptor signalling, antigen presentation, glycan-mediated T-cell regulation, and NF-κB-linked inflammation. Concordance with mixed linear models and genome-wide McNemar tests suggested that both additive and non-additive genetic effects shape the observed signal. These reproducible, albeit preliminary, markers outline a genomic foundation for breeding MAP-resilient goats and point to opportunities for reducing pathogen shedding at its source within a broader One Health strategy.

Keywords Paratuberculosis, Johne's disease, Machine learning–based GWAS, Host genetic resistance, Caprine genomics, One Health

Introduction

Mycobacterium avium subsp. *paratuberculosis* (MAP), the causative agent of paratuberculosis (Johne's disease) in ruminants, constitutes a critical One Health concern with direct implications for animal productivity, human health, and environmental safety. Infected hosts often remain asymptomatic for prolonged periods while persistently shedding MAP in milk, faeces, and pasture environments, enabling quiet but extensive contamination of farms and facilitating entry of the pathogen into the human food chain. This covert circulation contributes to substantial economic losses—particularly in regions

characterised by dense ruminant populations and sub-optimal control programmes—and heightens zoonotic concern amid growing interest in potential associations with chronic inflammatory disease in humans. Its environmental persistence, transboundary dissemination, and systematic under-diagnosis collectively pose escalating threats to public health, food security, and sustainable livestock systems, underscoring the need for integrated One Health strategies that unite animal surveillance, human disease monitoring, and environmental stewardship [1].

MAP pathogenesis reflects a dynamic interplay between host immunity and bacterial virulence factors, with the intestinal mucosa as the principal site of infection and granulomatous inflammation as the hallmark lesion. Clinically, affected ruminants exhibit progressive diarrhoea, weight loss, and eventual cachexia [2]. Diagnosis is hindered by an extended asymptomatic phase and the limited sensitivity of current assays—serology, faecal culture, and PCR—particularly in subclinical carriers [3]. Beyond the veterinary context, public health relevance is amplified by reported associations with Crohn's disease [4] and autoimmune conditions including type 1 diabetes, rheumatoid arthritis, Hashimoto's thyroiditis, and multiple sclerosis, potentially mediated through molecular mimicry [1, 5]. Asymptomatic shedding throughout the life of infected animals accelerates its global spread [6]. The organism's spore-like phenotype enables survival for months in barns, slurry, and surface water, and even persistence through pasteurisation, thereby contaminating bulk milk, dairy products, and infant formula [5]. Transmission through insects has also been documented [7].

The disease exhibits substantial geographic variation in prevalence; a comprehensive review across 48 countries revealed that in approximately half of the countries with available data, more than 20% of herds and flocks were infected with MAP [8]. Regional studies demonstrate marked heterogeneity, with true individual animal seroprevalence reaching 8.4% in sheep and 25.2% in goats in southern Spain, where herd-level seropositivity was detected in 66.3% of sheep herds and 90.0% of goat herds [9]. In Sicily, a large-scale serological survey revealed an overall apparent herd-level prevalence of 71.8% in sheep and 60.8% in goat farms, with animal-level prevalence of 4.5% and 5.1% in sheep and goats, respectively [10]. Systematic reviews from Latin America and the Caribbean reported animal-level prevalence of 16.0% in sheep and 4.3% in goats [11]. Studies from Inner Mongolia, China documented seroprevalence of 18.48% in sheep [12]. Notably, the disease remains particularly underreported in developing countries, especially Africa, where it is considered a neglected disease despite its significant

impact on rural communities dependent on small ruminant production [13].

In Türkiye, sheep seroprevalence ranges from 8.3% [14] to 48% [15]. A comprehensive survey of 2,257 animals from seven native and four composite breeds demonstrated marked breed effects, with rates ranging from 0% in Çine Çaparı sheep to 29.4% in Sakız, yielding a population mean of 7.3% and herd-level infection exceeding 90% [16]. Caprine paratuberculosis studies are scarce in Türkiye; a single field survey in Burdur Province reported 24% seropositivity in goats using ELISA [15].

Taken together, MAP is a globally pervasive and environmentally resilient pathogen that undermines livestock productivity, compromises food safety, and presents a growing public health risk. Its insidious subclinical course, continual shedding, and capacity for environmental persistence necessitate coordinated One Health solutions that span the animal–human–environment interface. In the absence of effective treatment and given the uncertain influence of the only licensed vaccine on shedding dynamics, attention has shifted toward long-term control strategies, particularly the identification of genetic determinants of resistance and susceptibility as a route to improving host resilience.

Host genetic resistance to MAP reflects a complex architecture shaped by innate recognition, cytokine regulation, and antigen presentation. In cattle, candidate-gene studies indicate that polymorphisms within pattern-recognition receptors and cytokine-modulating pathways—including *TLR1*, *TLR2*, *TLR4*, and *IL10RA*—alter the balance between inflammatory activation and immune tolerance [17, 18]. Genome-wide studies extend this view, highlighting additional loci linked to inflammasome signalling and interferon-mediated defence [19] and illustrating the polygenic nature of resistance.

In sheep, early evidence implicated *SLC11A1* and MHC-linked regions in modulating susceptibility [20]. Subsequent studies identified functional substitutions within *TLR1*, *TLR2*, and *TLR4* that modify innate recognition of mycobacterial ligands [21]. Genome-wide signals in *PCP4* and *CD109* [22] further suggest that both innate sensing and downstream immunoregulatory processes are integral to disease outcome.

Studies from Türkiye refine these insights by demonstrating that several globally proposed candidates show no association with MAP serostatus in native sheep populations [23, 24]. Conversely, a structurally significant amino-acid replacement within *TLR2* confers clear protection [16]. The absence of this variant in Turkish Saanen goats implies species-specific genetic routes to resistance.

Caprine research remains limited, yet available findings consistently point to antigen-presentation and phagosomal-transport pathways. Variation in *MHC II-DRB*

alleles [25] and microsatellite-linked polymorphisms of *SLC11A1* [26] highlight roles for T-cell priming and macrophage microbicidal activity. Preliminary genome-wide signals [27] further support a widely distributed genetic architecture in which resistance emerges from coordinated modulation of innate sensing, intracellular control, and adaptive immunity.

To extend current knowledge, we conducted the largest caprine MAP serosurvey undertaken in Türkiye. A total of 3,372 goats were sampled across four geographic regions—Marmara, Mediterranean, Central Anatolia, and Southeastern Anatolia—spanning 11 provinces and seven widely farmed native breeds (Hairy goat, Honamlı, Angora, Kilis, Turkish Saanen, Maltız, and Damascus). All animals were screened using an indirect ELISA, from which the case and control groups were derived. To minimise confounding, a matched-pair panel of 240 MAP-positive goats and 240 MAP-negative controls ($n=480$) was constructed through manual matching for farm, herd, breed, age, and sex, thereby controlling for geographic, climatic, and management effects, as well as breed-, age-, and sex-related influences in downstream genetic analyses.

Advances in analytic methodology are reshaping efforts to characterise host genetic resilience to MAP. Conventional GWAS approaches often struggle to detect small-effect variants, fail to capture nonlinear or non-additive relationships within the genome, and have limited capacity to account for higher-order gene–environment interactions [28, 29]. Machine learning (ML) has therefore emerged as a complementary tool, offering enhanced predictive performance, more effective prioritisation of candidate SNPs associated with susceptibility or resilience, and the ability to capture complex, non-linear relationships and interactions that may be overlooked by conventional linear approaches [30, 31].

To address these gaps and establish a rigorous foundation for genotype–phenotype inference, we employed a high-resolution genotyping platform (Illumina Goat 64 K BeadChip) coupled with stringent quality control and a model-independent Mutual Information (MI) approach to reduce dimensionality while preserving variants informative across linear and non-linear regimes. Building on this foundation, we developed a multi-algorithm machine-learning framework that integrates complementary modelling paradigms—including Linear/Generalised Linear Models (Logistic Regression L2, Elastic Net, Linear SVM), Probabilistic/Generative Models (Naive Bayes), Tree-Based Ensemble Learners (Random Forest, Extra Trees), and Gradient Boosting Algorithms (Gradient Boosting, XGBoost, LightGBM)—to capture a broad spectrum of genetic signals. Model performance was systematically evaluated using a suite of discrimination and calibration metrics across training, validation, and

independent test sets, with overfitting tightly controlled through predefined divergence thresholds.

To identify robust molecular predictors, feature importance was extracted using model-appropriate strategies and consolidated into a unified SNP ranking via weighted averaging, Borda count, and Kemeny–Young aggregation, incorporating persistence, rank stability, and bootstrap-based confidence. All analytical steps were rigorously structured to eliminate data leakage and ensure reproducibility. Together, this integrated framework provides a comprehensive and methodologically resilient approach for resolving the genomic determinants of MAP resistance, offering a principled bridge between statistical learning and biological interpretation.

Materials and methods

Sampling strategy and study populations

To capture the genetic and serological diversity of goats raised under Türkiye's heterogeneous husbandry systems, sampling was conducted across 36 farms located in 11 provinces representing four major geographical regions. This design ensured comprehensive coverage of the national goat population. From each of the seven constituent breeds, approximately 450–500 animals were selected. Only goats aged two years or older were included to ensure adequate time for seroconversion following potential MAP exposure. For serological testing, blood was collected from the jugular vein into gel tubes, and for genetic testing, into EDTA-containing tubes. Serum samples were separated immediately. Both whole blood in EDTA tubes and serum samples were placed in a -20°C deep freezer as soon as possible and stored until laboratory analyses were performed. Authorized permissions were obtained for all sampling procedures. After blood collection, all animals continued their routine management under standard husbandry conditions at their respective farms, and no animals were euthanized at any stage of the study. The distribution of sampled animals is summarised in Table 1.

Serological screening

Serological screening for paratuberculosis was performed on 3,372 goat samples using the Indirect Enzyme-Linked Immunosorbent Assay (indirect ELISA) with commercial kits (IDvet, ID Screen Paratuberculosis Indirect Screening Test, Grabels, France), following the manufacturer's protocol. Optical density (OD) was measured at 450 nm, and Sample-to-Positive percentage (SP%) values were calculated as:

$$SP\% = \frac{OD_{\text{sample}} - \overline{OD}_{\text{negative control}}}{\overline{OD}_{\text{positive control}} - \overline{OD}_{\text{negative control}}} \times 100$$

Table 1 The sampling distribution across breeds, provinces, and geographic regions

Breeds	n	Male	Female	Farm	Location (Provinces)	Geographic region
Hairy goat	500	17	483	6	Antalya, Burdur, Kahramanmaraş, Mersin	Mediterranean
Honamlı goat	464	11	453	6	Antalya, Burdur	
Damascus	470	22	448	6	Hatay	
Angora goat	486	22	464	6	Ankara, Siirt	Central Anatolia and Southeastern Anatolia
Kilis goat	499	10	489	4	Gaziantep, Kilis	Southeastern Anatolia
Turkish Saanen	475	6	469	4	Çanakkale	Marmara
Maltız goat	478	8	470	4	Kırklareli	Marmara
Total	3.372	96	3.276	36	11	4

Table 2 Distribution of the matched-pairs panel across breeds, ages, and herds

Breeds	Number of herds	Ages									Total pairs
		2	3	4	5	6	7	8	9	10	
Hairy goat	4	0	3	9	7	7	5	1	0	0	32
Honamlı	4	1	10	14	4	0	1	3	0	0	33
Angora	3	2	2	8	3	2	0	2	0	0	19
Kilis	4	2	17	15	5	1	0	0	0	0	40
Turkish Saanen	3	12	4	12	7	4	0	0	0	0	39
Maltız	4	1	5	17	10	3	0	3	0	1	40
Damascus	6	5	13	8	6	5	0	0	0	0	37
Overall	28	23	54	83	42	22	6	9	0	1	240

Tests were validated when the ratio of mean negative to mean positive control SP% was $\leq 1/5$. Samples with SP% $\leq 60\%$ were considered negative, $\geq 70\%$ positive, and 60–70% borderline. Of the total, ELISA failed in three samples, while the remaining 3,369 were successfully screened for paratuberculosis.

Construction of the case–control matched-pairs panel

To enable genotype–phenotype association analyses with maximal control over environmental and demographic confounding, a panel of 240 matched case–control pairs was constructed. Matching criteria included farm, herd, breed, age, and sex, such that each MAP-positive individual was paired with a MAP-negative individual raised under identical conditions. Prior to matching, all sero-positive and seronegative samples were ranked based on their SP% values. Strict thresholds were applied to maximise contrast: SP% ≥ 100 for inclusion as positive and SP% ≤ 10 for inclusion as negative. Samples with intermediate or borderline SP% values were excluded to avoid phenotype misclassification. The distribution of matched pairs by breed, herd, and age class is provided in Table 2.

Genotyping, quality control, and genotype imputation

Genotyping was conducted on the Illumina GoatSNP 64 K BeadChip, yielding an overall genotyping success rate of 0.999204. Quality control (QC) procedures were performed in PLINK v1.9. Sex chromosomes and SNPs lacking defined genomic positions (“chromosome 0”) were removed, followed by exclusion of duplicated SNP identifiers. SNP- and sample-level QC thresholds

included SNP call rate $> 95\%$, individual call rate $> 90\%$, minor allele frequency (MAF) $> 5\%$, and Hardy–Weinberg equilibrium p-value $> 1 \times 10^{-5}$. Linkage disequilibrium (LD) pruning was performed at $r^2 < 0.2$ to minimise redundancy. Missing genotypes were imputed using Beagle v5.0. Six individuals (3 matched pairs) were excluded during QC, reducing the panel from 480 to 474 individuals. After QC, the dataset consisted of 44,375 SNPs and 474 individuals (237 case–control pairs).

Feature preselection via mutual information

Rationale and theoretical basis

Given that the quality-controlled genotype matrix comprised 44,375 genome-wide SNP markers across 474 individuals, direct application of machine learning algorithms to this ultra-high-dimensional feature space would entail prohibitive computational burden and acute susceptibility to the curse of dimensionality, wherein the number of predictors vastly exceeds the sample size ($p \gg n$). To address this, mutual information (MI) was employed as a model-agnostic, filter-based feature selection strategy to reduce genomic dimensionality while retaining variation informative for phenotype prediction. Unlike conventional correlation-based filters, MI quantifies both linear and nonlinear statistical dependencies between SNP genotypes and binary disease outcomes, conferring a distinct advantage in complex, polygenic genomic architectures where epistatic and non-additive effects may contribute to phenotypic variance [32, 33]. Its invariance to monotonic transformations further ensures robustness to heterogeneous SNP encoding schemes and departures from

Gaussian phenotype distributions. Notably, by ranking markers according to their individual discriminatory capacity, MI-based filtering also attenuates the redundancy introduced by linkage disequilibrium, effectively prioritising tag SNPs that capture maximal phenotype-associated information content within correlated haplotype blocks [32, 34, 35].

Implementation within nested cross-validation

Feature preselection was performed using the `mutual_info_classif` function from `scikit-learn`, retaining the top ~1% of genome-wide SNPs (500 total). MI computation was embedded within a rigorously structured nested cross-validation (CV) design consisting of 5 outer folds and 4 inner folds, repeated across 10 independent random seeds (50 total test evaluations). All hyperparameter optimisation—including the number of neighbours used in the *k*-nearest-neighbour MI estimator and the size of the feature subset—was restricted strictly to inner folds to ensure proper separation between model selection and performance estimation.

A *k*-nearest-neighbour MI estimator was used to capture model-free dependencies between discrete genotype states and the binary phenotype. For each outer fold, optimal hyperparameters derived from the inner loop were used to recompute MI scores on the complete outer-training portion. Final MI rankings were computed by globally aggregating fold-wise scores across all outer folds and seeds using min–max normalisation.

Preservation of matched-pair integrity

All data partitioning procedures respected the structure of case–control matched pairs. Samples sharing a pair identifier were never separated across folds, ensuring that no MAP-positive individual was ever evaluated independently of the MAP-negative partner originating from the same farm, breed, age group, and sex. This design prevented information leakage, preserved biological dependency structures, and allowed explicit control over potential confounders influencing MAP dynamics. Pair-based constraints were enforced identically across inner and outer folds, guaranteeing that hyperparameter optimisation, feature selection, and final model evaluation all operated under equivalent biological matching conditions.

Adaptive hyperparameter optimization for mutual information-based feature selection

Hyperparameter optimization targeted two parameters: the number of nearest neighbors (`n_neighbors`) for KNN-based MI estimation and the number of top-ranked features to retain (*k*). The search space was defined by an adaptive grid scaled to dataset dimensions: `n_neighbors` candidates were set to {5, 7, 10}, balancing

the bias–variance tradeoff for the moderate sample size ($n=474$), while *k* candidates spanned $\pm 50\%$ of the target feature count (minimum 100, maximum equal to total markers), generating 9–15 combinations per fold. Each combination was evaluated using the mean normalized MI score across inner folds as the sole optimization criterion; stability and sparsity metrics were recorded as secondary diagnostics but excluded from the objective function. An early stopping mechanism terminated the search when no improvement exceeding 1% was observed for three consecutive evaluations. All feature scaling within the tuning loop was performed using locally fitted scalers never exposed to held-out data, ensuring genuinely out-of-sample hyperparameter selection.

Feature aggregation and stability estimation

Global MI profiles were derived by normalising and consolidating feature scores across all 50 independent test evaluations. Feature-selection stability was quantified through two complementary measures: (i) selection frequency across outer folds and seeds, and (ii) seed-consistency metrics capturing the reproducibility of SNP prioritisation under different random initialisations. Together, these metrics provided a rigorous assessment of signal robustness and ensured that downstream modelling relied on features consistently supported across resampling iterations.

Machine learning framework for SNP discovery

Model description

No single machine learning algorithm can adequately capture the full range of genetic effects that may underlie a complex disease trait. Additive polygenic signals, nonlinear epistatic interactions, and threshold effects each favour different modelling assumptions, and relying on one approach risks systematic blind spots. We therefore assembled a deliberately diverse ensemble of nine algorithms spanning three complementary families: penalised linear models (Ridge Logistic Regression, Elastic Net, Linear SVM) to detect additive allelic contributions under regularisation; tree-based ensemble methods (Random Forest, Extra Trees, Gradient Boosting, XGBoost, LightGBM) to capture higher-order SNP–SNP interactions without explicit feature engineering; and a probabilistic classifier (Naive Bayes) to serve as a computationally efficient, independence-assuming baseline against which more complex models can be benchmarked. By combining these three modelling families, the ensemble avoids commitment to any single hypothesis about the genotype–phenotype mapping and instead interrogates complementary dimensions of the genetic architecture governing paratuberculosis susceptibility—maximising the probability that both marginal and

combinatorial variant effects are identified within a single analytical framework.

Population structure modelling and covariate processing

Population structure was quantified using a PCA restricted to the pre-selected SNP panel, thereby preventing information leakage from genome-wide variation. All covariate handling—including demographic variables and PCs—was performed strictly within the nested cross-validation framework to preserve complete isolation between training and test partitions. Standardisation parameters were estimated exclusively from each training fold and subsequently applied to the corresponding test fold without recalibration. To avoid confounding and ensure stable effect estimation, demographic covariates and principal components were identified, validated for alignment, and standardised independently within every training split. The resulting scaled covariates were then horizontally merged with the normalised SNP features, producing fold-specific augmented matrices that jointly captured genomic structure and non-genomic predictors. This rigorous preprocessing pipeline ensured that inferred associations reflected genuine genetic contributions rather than artefacts arising from information leakage or improperly adjusted confounders.

Machine learning pipeline

A comprehensive machine learning pipeline was developed to identify genomic variants associated with paratuberculosis resistance in goat populations. The pipeline integrated nine classification algorithms spanning tree-based ensembles, gradient boosting methods, penalized linear models, and probabilistic classifiers, all evaluated within a rigorous nested cross-validation framework. Methodological integrity was maintained through systematic leakage prevention, fold-wise preprocessing, and multi-layered statistical validation, ensuring that performance estimates and feature importance rankings remained unbiased and reproducible across all stages of the analysis.

Hyperparameter optimisation

Hyperparameter optimization was performed independently for each classifier using the Optuna framework with the Tree-structured Parzen Estimator (TPE) as the sampling algorithm, which models the objective function as a ratio of Gaussian mixture densities to preferentially sample from promising regions of the search space. Each model was allocated 50 optimization trials, with an early stopping patience of 10 trials. A Hyperband pruner was applied to terminate unpromising trials after the second inner fold if intermediate scores indicated low likelihood of improvement over the current best. The optimization objective was balanced accuracy, selected for its

robustness to potential fold-level sampling fluctuations even under the balanced study design (237 cases, 237 controls). Model-specific search spaces were defined as follows: tree-based ensembles (Random Forest, Extra Trees, Gradient Boosting) were tuned over $n_{\text{estimators}}$ (200–800), max_depth (5–40 for bagging methods; 3–12 for boosting), min_samples_split (2–30), min_samples_leaf (1–15), max_features ($\{\sqrt{p}, \log_2 p, \text{all}\}$), and split criterion ($\{\text{Gini}, \text{entropy}\}$); gradient boosting variants (XGBoost, LightGBM) additionally optimized learning_rate (0.005–0.3, log-scale), subsample (0.5–1.0), colsample_bytree (0.5–1.0), and L1/L2 regularization penalties (reg_alpha , reg_lambda : 0–10), with LightGBM further tuning num_leaves (20–150) and min_child_samples (5–100); penalized linear models (Logistic Regression L2, Elastic Net, SVM Linear) were tuned over inverse regularization strength C (10^{-5} – 10^3 , log-scale), with Elastic Net additionally optimizing the L1/L2 mixing ratio l1_ratio (0–1); and Naive Bayes optimized var_smoothing (10^{-12} – 10^{-4} , log-scale). Given the balanced class distribution, no class-level reweighting or cost-sensitive adjustments were activated during optimization.

Nested cross-validation and leakage prevention

A fully nested design comprising 5 outer folds $\times$ 5 seeds (25 independent evaluations) ensured unbiased performance estimation. Case–control matched pairs were preserved in all splits, maintaining biological dependencies while preventing inadvertent leakage from farm, breed, age, or sex structure. Inner folds were used exclusively for hyperparameter optimisation; outer folds were reserved for independent testing. All preprocessing—standardisation, covariate alignment, PCA application—occurred independently within each fold. No information from any test partition influenced training operations.

Performance metrics—including AUC, balanced accuracy, MCC, F1-score, recall, and specificity—were computed for each of the nine machine-learning models across 25 independent test datasets, and the aggregated results and confidence intervals summarised model-level stability.

Feature importance estimation

Feature importance was extracted using model-native criteria: Gini importance or gain for tree-based models, standardised coefficients for linear models, and permutation importance for models lacking intrinsic interpretability. Each metric was normalised to the [0,1] interval to enable cross-model comparability. Importances were computed exclusively within the validation folds of the inner CV to avoid leakage from outer test sets. The resulting fold-specific matrices (features $\times$ 25 evaluations) were aggregated to yield mean effect sizes and stability indices,

including variance, Spearman correlations, and Jaccard similarity across folds.

Statistical validation and quality control

Multiple validation layers were embedded throughout the pipeline:

- (i) train–test independence was verified using automated overlap detection.
- (ii) overfitting was monitored via performance gaps exceeding 0.05 AUC or 0.07 balanced accuracy.
- (iii) calibration quality was evaluated through Brier scores and calibration slopes within the acceptable 0.9–1.1 range.
- (iv) consensus feature rankings underwent post-hoc permutation testing (10,000 iterations) with Benjamini–Hochberg correction ($q < 0.05$).

Global leakage and overfitting safeguards

Pipeline integrity was ensured through stringent safeguards:

- (i) strict isolation of training and test folds,
- (ii) fold-specific scaling and covariate handling,
- (iii) nested cross-validation for unbiased hyperparameter selection,
- (iv) automated flagging of models exhibiting excessive train–test divergence, and
- (v) calibration-based reliability assessments.

SNP discovery methodology

Multi-method consensus framework

To derive a stable and generalisable set of predictive variants, we constructed a multi-method consensus framework integrating three complementary aggregation strategies—weighted model-based scoring, Borda count ranking, and an approximate Kemeny–Young consensus. By combining direct importance estimation with rank-oriented and pairwise-preference methods, this framework reduces the idiosyncrasies of individual models and yields robust cross-model feature prioritisation.

Performance-driven and diversity-aware model weighting

Composite performance metrics

Each model's contribution began with a composite validation score that blended three elements: discriminatory power (captured through AUC), sensitivity to class imbalance (balanced accuracy), and precision–recall efficiency (F1 score). These components were combined in fixed proportions, with AUC receiving the highest weight, followed by balanced accuracy and then F1.

To account for performance reliability, we penalized models whose AUC values fluctuated substantially across cross-validation folds. Models exhibiting large variance had their contribution proportionally reduced. The product of the composite score and this stability penalty defined a model's base weight.

Diversity adjustment

To ensure that the ensemble did not overweight highly similar models, we quantified redundancy by computing pairwise correlations between each model's feature-importance rankings. A diversity score was then assigned to each model based on how weakly correlated it was with the remainder of the ensemble. Models providing more independent information received higher scores.

Final model weights combined the base (performance-driven) weight with the diversity component, using a heavier emphasis on the former. These weights were subsequently normalised so that their total sum equalled one.

Rank aggregation approaches

Weighted importance estimation

For each feature, we averaged the normalised importance values provided by all models, weighting each model's contribution according to its final ensemble weight. This produced the primary “weighted consensus” importance estimate.

Borda count consensus

To incorporate ordering stability, each feature received a Borda score reflecting its relative position in each model. These scores were aggregated across models using the ensemble weights and normalised to a common scale.

Kemeny–young pairwise-optimal consensus

We also employed an approximate Kemeny–Young procedure to quantify how consistently one feature was preferred over another across models. Summing these weighted pairwise preferences produced a global Kemeny score per feature. Due to computational constraints, Kemeny scoring was restricted to the top 100 features identified by the weighted consensus method.

Final composite ranking

The three ranking strategies were integrated as:

$$\text{final (f)} = 0.40 (\text{weighted}) + 0.30 (\text{Borda}) + 0.30 (\text{Kemeny}),$$

balancing direct score magnitude, rank stability, and pairwise-optimal ordering. This yielded a robust, cross-model consensus list suitable for downstream genomic interpretation.

Permutation-based statistical validation and persistence threshold

False-discovery control was performed using permutation-derived p-values based on logistic-regression AUCs evaluated under 5-fold cross-validation, benchmarked against null distributions generated via Westfall–Young minP permutations (10,000 iterations applied to the top 100 SNPs). Multiple testing correction followed the Benjamini–Hochberg procedure ($q < 0.05$). All permutation procedures were executed strictly on the outer test folds to prevent information leakage. SNPs surpassing the Benjamini–Hochberg threshold were subsequently filtered using a persistence cutoff of > 0.25 , a stability metric that aggregates the model-specific recurrence of high-importance rankings across outer-fold splits (25 folds in total) into a single consensus score.

The analytical workflow, summarized in Fig. 1, illustrates the transition from initial data refinement to the final identification of significant markers. This framework coordinates feature selection and model optimization across multiple algorithmic architectures to ensure a stable consensus. By linking independent performance evaluations with empirical significance testing, the pipeline provides a systematic basis for prioritizing SNPs that remain consistent across diverse computational approaches. The diagram outlines the hierarchical relationship between data partitioning, ensemble-based ranking, and the final discovery threshold used in this study.

Integrative validation of ML-derived signals via conventional GWAS frameworks

To benchmark the association signals identified by the ML ensemble against conventional statistical genetics approaches, two complementary genome-wide analyses were conducted using the complete SNP dataset. A classical mixed linear model (MLM) was implemented in GEMMA [36], with breed included as a covariate to account for population structure and potential confounding effects. In parallel, a genome-wide McNemar test was performed on matched case–control pairs using custom Python scripts developed by the authors. These parallel analyses enabled systematic cross-method comparison and evaluation of concordance between machine-learning–derived predictions and hypothesis-driven association testing frameworks in identifying SNPs associated with MAP susceptibility.

Genomic annotation, gene enrichment, and pathway analysis

Genomic annotation of significant SNPs was performed using the ARS1 reference assembly through the Ensembl platform, Genome Data Viewer, and Genome Browser. Genes located within ± 200 kb of each significant SNP

were subjected to functional enrichment and pathway analysis using ShinyGO database, incorporating all available databases for the *Capra hircus* genome. A false discovery rate of 0.05 was applied to identify significantly enriched terms. All visualisations and graphical outputs were generated using ShinyGO.

Results

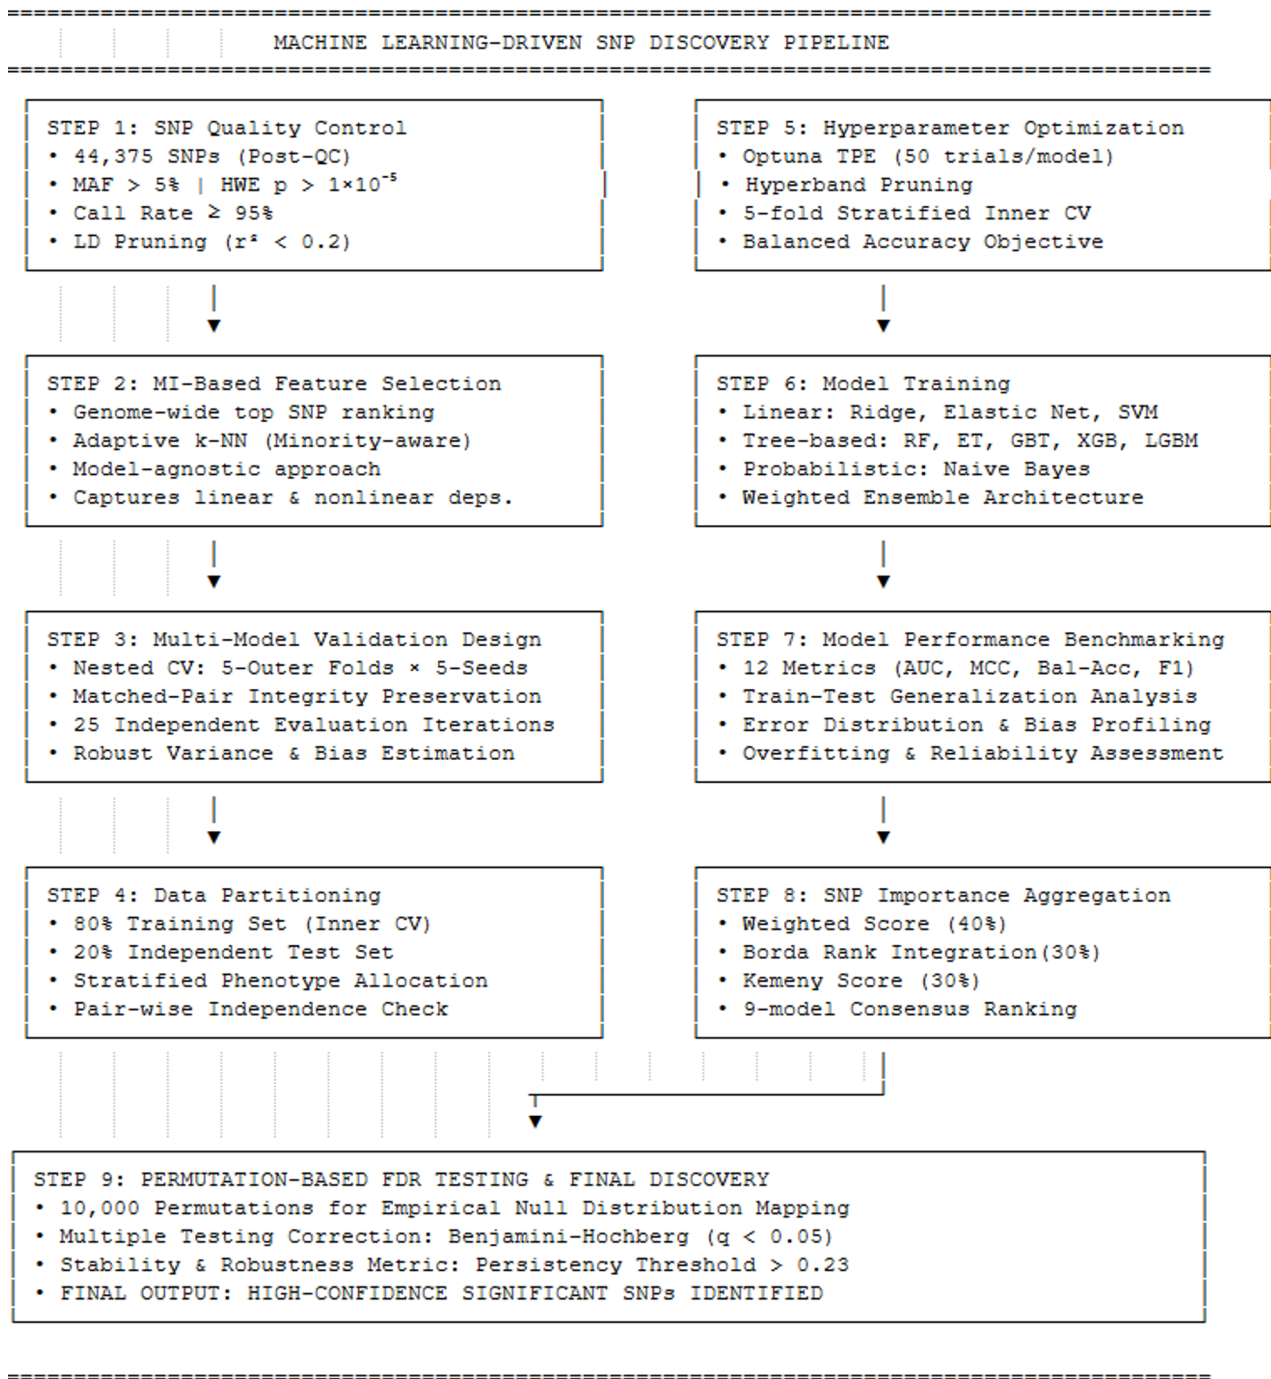

Serological survey results

Serological screening across seven indigenous goat breeds—based on 3,369 successfully tested animals from 36 herds spanning four geographic regions (Fig. 2)—revealed a heterogeneous yet broadly coherent pattern of MAP exposure. The mean individual seroprevalence was 13.95%, with breed-level estimates ranging from 8.6% (Hairy goat) to 25.41% (Angora). At the herd level, a prevalence of 95.55% highlighted the deep and widespread establishment of MAP in Türkiye's goat production systems. Although absolute seropositivity differed among breeds, the near-universal presence of positive animals across herds indicated that MAP circulation is extensive and persistent.

Across the 240 matched pairs—constructed according to herd, breed, age, and sex and subsequently used to generate the dataset for genetic analyses—the seronegative group exhibited a mean Sample-to-Positive (SP) value of 3.5%, whereas the seropositive group showed a markedly higher mean of 202.0 (Fig. 3). This clear separation between positive and negative animals provided a reliable foundation for downstream analyses, ensuring consistency and interpretive confidence.

Discriminative performance of preselected features

Comparative analysis between Top 500 SNPs and remaining variants demonstrates exceptional discriminative capacity across all quality metrics. Selected SNPs exhibit four-fold elevated mean MI scores (median ~ 0.28 vs. ~ 0.05) (Fig. 4a) with superior cross-fold stability (Fig. 4b), as evidenced by lower coefficient of variation values (~ 0.30 vs. ~ 0.7) (Fig. 4c). The selection frequency distribution reveals that Top 500 SNPs span 0.4–1.0 (Fig. 4d) indicating consistent prioritization across cross-validation iterations, while non-selected variants cluster near zero (< 0.05). Perfect seed consistency (1.0) for selected features contrasts sharply with near-zero reproducibility (~ 0.05) for remaining variants (Fig. 4e), confirming deterministic convergence to biologically relevant markers independent of stochastic initialization. Notably, the coefficient of variation (Fig. 4c) displays a bimodal pattern where Top 500 SNPs concentrate at lower CV values (~ 0.30), signifying superior stability, while the remaining variants exhibit higher relative variability (~ 0.60), reflecting their inconsistent and likely spurious signals across different data partitions. These

diverse modelling frameworks for paratuberculosis susceptibility.

Test-set balanced accuracy ranges from 0.947 to 0.971, peaking with Random Forest (0.971) and reaching its minimum with SVM Linear (0.947). Naive Bayes (0.969), LightGBM (0.967), Gradient Boosting (0.967), and XGBoost (0.967) form a narrow 0.2% performance cluster, indicating functional equivalence. Naive Bayes again shows the smallest train–test gap ($\Delta=0.007$), whereas Elastic Net displays the largest decline ($\Delta=0.044$), suggesting sensitivity to regularisation or insufficient model complexity. The clustering of five models within a 0.44% accuracy window indicates that performance differences

among nonlinear classifiers are minimal, while the comparatively lower scores of linear models suggest that additional modelling flexibility may be beneficial for capturing complex decision boundaries.

F1-scores closely mirror balanced accuracy, spanning 0.947–0.971 on the test set. Random Forest leads (0.971), followed by Naive Bayes (0.969) and Gradient Boosting (0.968). Train–test F1 divergences range from 0.007 to 0.044, with Naive Bayes and XGBoost showing exceptional stability, while Elastic Net, SVM Linear, and Logistic Regression L2 exhibit larger performance drops, consistent with known limitations of linear decision functions in representing complex feature interactions. The systematic F1 reductions observed predominantly in linear classifiers suggest that MAP-associated genotype–phenotype relationships may involve interaction patterns or nonlinear structures that are more effectively captured by flexible modelling approaches.

The Matthews Correlation Coefficient (MCC), a class-imbalance–invariant metric integrating all confusion matrix components, ranges from 0.895 to 0.944 on the test set. Random Forest (0.944) and Naive Bayes (0.940) show the strongest agreement between predictions and ground truth, followed by Gradient Boosting, XGBoost, and LightGBM (all 0.936). Logistic Regression L2, Elastic Net, and SVM Linear occupy the lower boundary (0.900, 0.900, and 0.895), indicating reduced capacity to optimise all classification quadrants concurrently. The 4.4% MCC gap between the best nonlinear model (Random Forest) and the best linear models (Logistic Regression L2 and

Fig. 4 Distribution of MI metrics for the Top 500 SNPs selected by the Mutual Information Algorithm versus all remaining excluded SNPs. The Fig. 4 demonstrates that the top 500 SNPs exhibit consistently higher informativeness, lower variability, and near-perfect reproducibility compared with excluded variants, thereby confirming the stability and biological relevance of the preselected feature set. **a** mean_mi_score: Mean Mutual Information across resampling iterations, indicating overall informativeness of each SNP. **b** std_mi_score: Standard deviation of MI values, reflecting the stability of each SNP's information contribution across iterations. **c** cv_mi_score: Coefficient of variation of MI scores, capturing relative dispersion and highlighting features with unstable or noise-driven signal. **d** selection_frequency: Proportion of resampling runs in which each SNP was selected, representing robustness and repeatability of selection. **e** seed_consistency: Consistency of SNP selection across different random seeds, quantifying reproducibility of feature importance under stochastic variation

Elastic Net) highlights measurable differences in overall classification quality across modelling strategies.

Train–test MCC degradation spans 0.013–0.087, representing a 6.7-fold variation in generalisation stability. Naive Bayes, XGBoost, and Random Forest maintain MCC loss below 5%, whereas Elastic Net, SVM Linear, and Logistic Regression L2 approach or exceed 6.5%. Gradient Boosting and Extra Trees exhibit intermediate degradation, reflecting moderate capacity–complexity trade-offs. The alignment between high test-set performance and relatively low degradation suggests that the strongest-performing models maintain stable generalisation behaviour across datasets.

Test-set precision varies from 0.949 to 0.970, with Random Forest and Naive Bayes achieving the highest positive predictive value (0.970), corresponding to minimal false-alarm rates. Precision train–test gaps range from 0.004 to 0.043, with Naive Bayes showing exceptional stability and Gradient Boosting and Elastic Net the greatest volatility, likely due to amplification of training-set idiosyncrasies inherent to sequential error correction. From a practical breeding perspective, the consistently high precision across all models (> 0.949) indicates a low expected false-positive rate when identifying MAP-susceptible animals.

Recall (sensitivity) spans a wider range than other performance metrics (0.947–0.983), peaking with XGBoost (0.983), followed by Gradient Boosting (0.982) and LightGBM (0.980), thereby identifying gradient-based ensembles as particularly effective when false-negative costs dominate. Elastic Net (0.952) and SVM Linear (0.947)

exhibit the lowest recall, consistent with the limited representational flexibility of linear decision boundaries. Train–test recall degradation remains modest across models ($\Delta = 0.005$ –0.045), with XGBoost ($\Delta = 0.005$) and Naive Bayes ($\Delta = 0.009$) showing exceptional generalisation, whereas Elastic Net ($\Delta = 0.045$) and Logistic Regression L2 ($\Delta = 0.038$) demonstrate more pronounced decline. These patterns suggest that gradient-based ensembles may offer advantages in settings prioritising the detection of susceptible animals.

Recall and specificity exhibit balanced performance across classifiers, spanning 0.947–0.983 and 0.947–0.968, respectively, with no pronounced trade-offs between true positive and true negative rates. Gradient Boosting, XGBoost, and LightGBM attain the highest recall (0.982, 0.983, and 0.980), favouring these ensembles for recall-critical settings, whereas Naive Bayes achieves maximal specificity (0.968), highlighting its strength in minimising false positives. The absence of a marked recall–specificity trade-off suggests that the selected SNP features differentiate susceptible and resistant phenotypes with comparable clarity across modelling frameworks.

Mean prediction confidence displays a marked bimodal distribution (0.661–0.997). Naive Bayes yields near-maximal confidence (0.997) with negligible train–test degradation, consistent with well-calibrated posterior probabilities under conditional independence assumptions. Gradient Boosting similarly shows high confidence (0.988) with minimal volatility. In contrast, Random Forest exhibits systematic underconfidence (0.661), representing a 33.7% deficit relative to Naive Bayes,

Table 3 Comparative performance metrics of machine learning classifiers on training and test sets

AUC (Area Under Curve): Model's discrimination power; ability to distinguish between positive and negative classes (0-1 range, higher=better)

Balanced Accuracy: Mean of sensitivity and specificity, providing equal weight to both classes

F1: Harmonic mean of Precision and Recall; overall performance measure balancing both metrics

MCC (Matthews Correlation): Balanced classification quality using all confusion matrix elements

Precision: Proportion of positive predictions that are actually correct; measures exactness

Recall (sensitivity): Proportion of actual positives correctly identified; measures completeness

Specificity: Proportion of actual negatives correctly identified; true negative rate

Confidence Mean: Average prediction confidence score across all samples

Confidence Std: Standard deviation of confidence scores; measures prediction uncertainty variation

Confidence Min: Lowest confidence score among all predictions

Confidence Max: Highest confidence score among all predictions

Brier Score: Mean squared difference between predicted probabilities and actual outcomes (0-1, lower=better)

attributable to probability regression induced by ensemble averaging. Gradient-based ensembles combine high confidence with strong discrimination, with XGBoost (0.952) and LightGBM (0.974) offering robust probability estimates alongside accurate classification. These differences in confidence structure may influence downstream threshold-based decision strategies in genomic selection contexts.

Confidence variability ranges from 0.017 to 0.119, with Naive Bayes showing minimal dispersion (0.017) and Elastic Net (0.117) and SVM Linear (0.119) exhibiting approximately sevenfold greater heterogeneity, reflecting instability of probability estimates under linear decision boundaries. The relatively low variability observed in Naive Bayes and gradient-based ensembles indicates consistent probability estimation across samples.

Brier scores span 0.029–0.137, with four models forming a distinctly superior calibration cluster at or below 0.031: Naive Bayes (0.029), LightGBM (0.030), XGBoost (0.030), and Gradient Boosting (0.031). This group achieves a calibration advantage of up to 79% over the worst-performing model, Random Forest (0.137; relative improvement: $(0.137 - 0.029) / 0.137 \approx 0.79$), underscoring a clear separation between well-calibrated and poorly calibrated models. Notably, the inclusion of Naive Bayes alongside three gradient-based ensembles in this elite tier suggests that strong probabilistic calibration can be attained through fundamentally different modelling

assumptions—parametric distributional inference as well as iterative residual correction. Extra Trees occupies an intermediate position (0.054), while linear models show progressively degrading calibration (SVM Linear 0.050, Logistic Regression L2 0.106, Elastic Net 0.117), and Random Forest records the poorest test-set calibration (0.137). The convergence of these four structurally diverse models at Brier scores below 0.031 confirms that strong discriminative performance does not automatically confer well-calibrated probability estimates, but that certain model families achieve both simultaneously.

Train-test performance differences across 25 folds

The composite overfitting metric integrates multiple performance gaps into a single quantitative index of generalisation stability. For each fold, discrepancies between training and test performance are calculated for AUC, balanced accuracy, and F1 score, capturing complementary dimensions of potential overfitting. These gaps are then combined using a weighted scheme that assigns the greatest emphasis to AUC, followed by balanced accuracy and F1, producing a unified score that reflects the overall extent of performance inflation on the training data. During analysis, any fold exceeding the weighted overfitting threshold of 0.05 was excluded from further evaluation. The resulting composite measure is interpreted using predefined thresholds that distinguish acceptable generalisation from moderate or pronounced overfitting,

Fig. 5 Variability of train–test metrics across 25-fold cross-validation. Variability of train–test performance metrics across 25-fold nested cross-validation for nine ML models: **a**, Random Forest; **b**, Gradient Boosting; **c**, Logistic Regression L2; **d**, Elastic Net; **e**, SVM Linear; **f**, Naive Bayes; **g**, XGBoost; **h**, LightGBM; **i**, Extra Trees. The composite overfitting metric integrates AUC, balanced accuracy, and F1 train–test gaps into a unified index. Folds exceeding the 0.05 threshold were excluded

enabling a clear and systematic assessment of model stability across folds (Fig. 5).

Cross-model feature importance concordance analysis

To quantify cross-algorithmic consistency in genomic feature prioritization, we constructed a comprehensive feature importance correlation matrix spanning all nine classification architectures. For each model, fold-averaged feature importance scores were computed, yielding a single importance value per SNP. Pairwise linear agreement was assessed via Pearson’s correlation coefficient applied to aligned SNP-level importance vectors, with only shared SNPs retained and missing values excluded.

The resulting symmetric 9×9 matrix with unity diagonal elements is visualized as a heatmap (Fig. 6).

The correlation structure reveals pronounced architectural clustering. Tree-based ensemble methods—Random Forest, Gradient Boosting, Extra Trees— and Naive Bayes demonstrate exceptionally high concordance ($r=0.993\text{--}0.999$), with Gradient Boosting–Extra Trees achieving near-perfect agreement ($r=0.999$). This convergence indicates that despite divergent algorithmic mechanisms, these methods identify substantively identical genomic signal structures.

Among linear models, Logistic Regression L2 and Elastic Net demonstrate strong mutual agreement ($r=0.980$),

Fig. 6 Cross-model feature importance correlation matrix. Heatmap Figure demonstrated that cross-model feature importance correlation matrix (Pearson’s r) across nine ML classification architectures. Despite their distinct algorithmic foundations, tree-based ensembles (Random Forest, Gradient Boosting, and Extra Trees) and the probabilistic Naive Bayes classifier form a high-concordance cluster ($r = 0.993\text{--}0.999$), indicating convergence on shared genomic signal structures despite different algorithmic mechanisms. Linear models (Logistic Regression L2, Elastic Net, SVM Linear) exhibit lower inter-family concordance ($r = 0.468\text{--}0.980$), reflecting the fundamental distinction between additive and interaction-dependent feature attribution

indicating substantial concordance in feature attribution despite their different regularization strategies. However, both exhibit markedly reduced concordance with SVM Linear ($r=0.468\text{--}0.472$), suggesting that margin-based optimization diverges fundamentally from likelihood-based linear frameworks in feature attribution patterns. This internal heterogeneity within the linear model family underscores that algorithmic paradigm—margin maximization versus likelihood optimization—exerts greater influence on feature importance rankings than regularization architecture alone.

On the other hand, linear architectures—Logistic Regression L2, Elastic Net, and SVM Linear—demonstrate substantially diminished concordance with tree-based methods ($r=0.468\text{--}0.671$). Elastic Net manifests the most pronounced divergence ($r=0.468\text{--}0.660$), potentially reflecting dual-penalty regularization's aggressive coefficient shrinkage for correlated features. This systematic linear-nonlinear discordance stems from fundamental representational constraints: linear models assign global importance weights invariant to feature interactions, whereas tree-based methods capture interaction-dependent feature salience through recursive partitioning.

Naive Bayes occupies a distinctive position within the correlation landscape: it aligns exceptionally well with tree-based ensembles ($r=0.993\text{--}0.997$ with Random Forest, Gradient Boosting, and Extra Trees), yet shows only moderate concordance with linear models ($r=0.616\text{--}0.865$ with Elastic Net and Linear SVM). This dual concordance pattern positions Naive Bayes as effectively bridging probabilistic and decision-boundary paradigms through its conditional independence architecture. Its near-perfect alignment with nonlinear methods suggests that probabilistic feature attribution naturally captures interaction structures, while its sustained—albeit attenuated—linear model agreement reflects shared reliance on feature-level marginal associations.

Significant markers identified through ensemble machine learning

Using an ensemble machine learning strategy that integrated nine models and employed extensive permutation testing ($n=10,000$), a total of 31 genomic loci were identified as having high predictive importance, each exceeding a precision threshold of 0.25. These SNPs showed consistent performance across multiple ranking approaches, with composite scores between 0.794 and 1.000, indicating stable and reproducible associations. Their chromosomal distribution was uneven, with notable clustering on chromosomes 2, 6, 11, and 21, suggesting potential functional concentration in these regions (Table 4).

Among these loci, snp4242-scaffold1131-545695 on chromosome 6 stood out, achieving maximum

normalized values across both Borda and Kemeny rankings (1.000) and exhibiting high rank stability (0.96), making it the most influential marker. Additional variants on chromosome 6—such as snp18252-scaffold1850-148547 and snp36198-scaffold433-398052—also ranked highly, with weighted normalized scores above 0.85 and strong persistence values (0.40–0.76), further highlighting the relevance of this chromosome. Chromosome 11 similarly contained several high-impact loci, including snp42545-scaffold564-283910 and snp17821-scaffold185-652809, both of which showed composite scores over 0.93 and substantial rank stability.

Combined with rank stability coefficients generally above 0.70, these results support the view that the observed associations are biologically meaningful rather than random. A subset of loci on chromosomes 2, 4, and 15 showed strong weighted normalized scores but moderate persistence levels, suggesting potential context-dependent or epistatic contributions that merit further investigation. Overall, the distributed yet functionally aligned set of loci provides a solid basis for follow-up mechanistic research and potential translational applications.

The ensemble-derived metrics shown in Fig. 7 provide a consistent visual distinction between SNPs classified as significant (blue; $\text{FDR } q < 0.05$) and non-significant (orange; $\text{FDR } q > 0.05$), with the normalised (“norm”) scores generally concentrated near the upper range for the significant group. In panel a, the normalised weighted score exhibits clear separation, with significant SNPs clustered tightly at high values, while non-significant SNPs are more dispersed and substantially lower. Panel b displays a similar pattern in the normalised Borda score, where significant SNPs show minimal variance and consistently high values, reflecting strong agreement across models. Panel c shows an even more pronounced contrast in the normalised Kemeny score, as non-significant SNPs exhibit wide variability and frequent near-zero values, suggesting inconsistent model support. In panel d, the normalised composite score effectively synthesises these indicators and maintains the strong separation between groups. Panel e demonstrates that raw rank stability is high and concentrated for significant SNPs—indicating stable ordering across folds—whereas non-significant SNPs exhibit much broader spread. Finally, panel f shows that raw persistence, representing the proportion of folds in which a SNP is selected, declines sharply for non-significant SNPs, while significant SNPs appear persistently across folds. Together, these panels present a coherent and objective multimetric pattern that differentiates SNPs with consistent model support from those without.

Table 4 Genomic variants with high predictive importance identified by ensemble machine learning

Weighted score: SNP's consensus importance derived from model-weighted averaging of normalized importances

Borda score: Rank-based consensus score computed via weighted Borda count across all model rankings

Kemeny score: Pairwise-rank aggregation score reflecting the SNP's position under the Kemeny-Young rule

Composite score: Integrated ensemble metric combining weighted, Borda and Kemeny scores (40 %, 30 %, 30 %) to produce the final consensus importance value for each SNP

Persistence: a stability metric that aggregates model-specific consistency of high importance rank across outer-fold splits into a single consensus score for each SNP

Rank stability: normalized rank consistency across models, where lower variance in feature ranking yields higher stability for the consensus SNP list

Fig. 7 Multimetric ensemble profiling of significant and non-significant SNPs. Figure 7 illustrated that multimetric ensemble profiling comparing significant (FDR $q < 0.05$; blue) and non-significant (FDR $q > 0.05$; orange) SNPs across six complementary metrics: **a** normalised weighted score; **b** normalised Borda score; **c** normalised Kemeny score; **d** normalised composite score; **e** raw rank stability; **f** raw persistence. Significant SNPs show consistently higher values, lower dispersion, and stable selection across folds, confirming robust cross-model support

Inter-model concordance patterns in top-50 SNP prioritization

Pairwise overlap coefficients were computed for the top 50 importance-ranked SNPs across all nine classifiers to evaluate inter-model agreement in feature prioritization (Fig. 8). The highest concordance was observed between Logistic Regression L2 and Elastic Net (0.840), consistent with the shared L2 regularization penalty that governs both algorithms' coefficient shrinkage behavior. Random Forest and Extra Trees exhibited the second-highest overlap (0.720), reflecting the architectural similarity between these two bagging-based ensemble methods. XGBoost displayed the broadest concordance profile among all classifiers, sharing 50.0% of its top markers with both LightGBM and Extra Trees, 48.0% with Random Forest, 40.0% with Gradient Boosting, and 34.0% with each of the regularized linear models—positioning it as the most connected node in the inter-model agreement network. Within the boosting subfamily, LightGBM and Gradient Boosting shared 50.0% of their top-50 selections, while LightGBM showed notably lower agreement with the linear classifiers (0.160 with both Logistic Regression L2 and SVM Linear). SVM Linear produced the weakest overall concordance, with overlap coefficients ranging from 0.160 to 0.300, suggesting that its maximum-margin decision boundary prioritizes a largely distinct set of genomic regions. Naive Bayes exhibited uniformly low-to-moderate agreement across all comparisons (range: 0.160–0.320), with its highest overlap observed against Elastic Net (0.320) and Gradient Boosting (0.260). The heatmap reveals a clear block-diagonal architecture in which tree-based ensembles (Random Forest, Extra Trees, XGBoost, LightGBM, Gradient Boosting) and regularized linear models (Logistic Regression L2, Elastic

Net) form two internally concordant clusters, with limited cross-family overlap.

Cross-model concordance and benchmarking of association signals

To assess cross-method consistency in SNP prioritisation, the overlap among the top 50 variants identified by the ML ensemble and the two genome-wide association frameworks was examined. Substantial concordance was observed across approaches, indicating that a core subset of loci was consistently prioritised despite differences in analytical strategy. Specifically, 24 SNPs overlapped between the ML ensemble and the MLM, while 31 SNPs were shared between the ML ensemble and the genome-wide McNemar analysis. Notably, 15 SNPs were jointly supported by all three approaches, representing the most robust candidate signals associated with MAP susceptibility (Fig. 9). In addition, 10 SNPs were uniquely identified by the ML ensemble, suggesting the potential detection of association patterns not captured by conventional statistical models. While linear statistical frameworks and machine-learning approaches rely on different modelling assumptions, the observed convergence—together with ML-specific signals—supports the view that MAP-associated genotype–phenotype relationships may involve both linear effects detectable through traditional association testing and more complex, potentially non-linear patterns captured by ensemble learning methods. These findings highlight methodological complementarity and reinforce the value of integrative cross-model comparison in resolving the genetic architecture of MAP susceptibility.

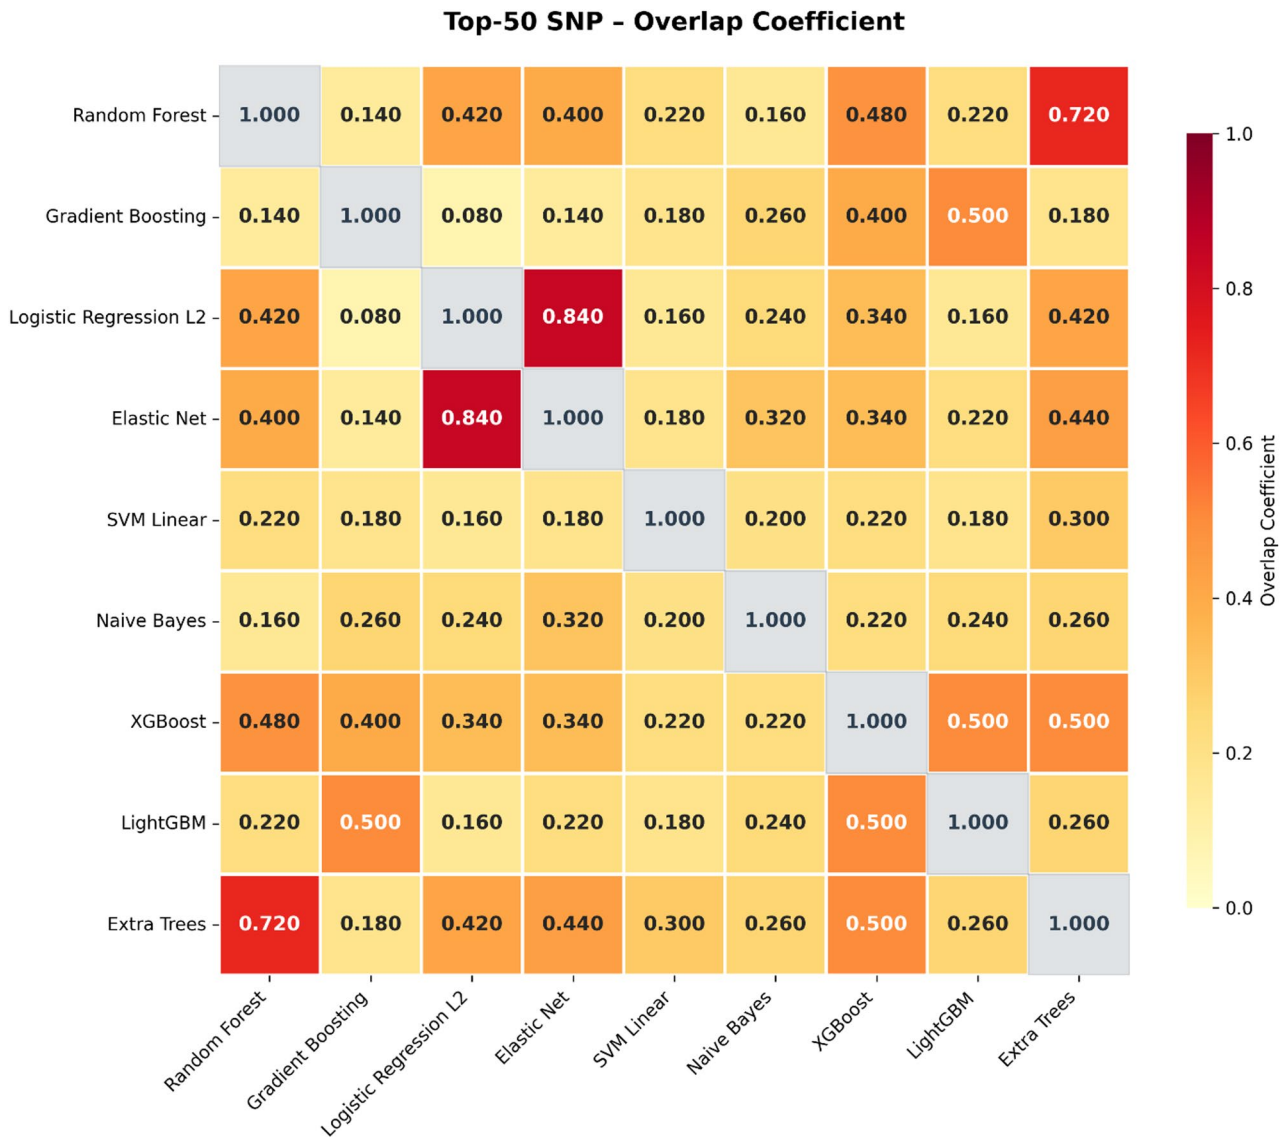

Fig. 8 Pairwise overlap coefficients for the top-50 importance-ranked SNPs across nine machine learning classifiers. In the Figure 8, each cell represents the overlap coefficient between two models' top-50 SNP lists. Values closer to 1.0 (dark red) indicate high marker agreement; values closer to 0 (light yellow) indicate largely non-overlapping selections

Gene functional annotation, GO-term enrichment, and pathway analysis

Across the genome, 31 significant SNPs were identified on 16 chromosomes, with the vast majority located in intergenic regions (Table 5). Only four variants fell within intronic sequences: *CACNA2D1* on chromosome 4, *RGS6* on chromosome 10, *BUB1* on chromosome 11, and *ENSCHIG00000014388* on chromosome 15. The remaining 27 SNPs were intergenic but frequently positioned within ± 200 kb of biologically relevant genes. Notably, several mapped near immune-related loci, including interferon-stimulated genes (*IFI44*, *IFI44L*, *IFI27L2*) and members of the interleukin receptor cluster (*IL1R1*, *IL1RL2*, *IL18R1*, *IL18RAP*).

Additional associations were observed adjacent to a dense serpin gene cluster on chromosome 21 (*SERPINA1*, *SERPINA6*, *SERPINA10*, *SERPINA11*, *SERPINA12*, *SERPINA14*), highlighting a region involved in regulating innate immunity, inflammation, hormone transport, coagulation balance, metabolic homeostasis, and reproductive immunomodulation.

The predominance of intergenic variants suggests that regulatory elements—rather than alterations in coding sequence—likely drive the observed associations. It is also plausible that these SNPs are in high linkage disequilibrium with functional coding variants in nearby genes, thereby serving as proxies for causal mutations.

Fig. 9 Cross-model overlap structure of benchmark association signals. UpSet plot showing overlaps among the top 50 SNPs identified by the ML ensemble, MLM, and genome-wide McNemar analyses. Fifteen SNPs were shared by all three approaches; pairwise overlaps included 24 SNPs (ML–MLM) and 31 SNPs (ML–McNemar), with 10 SNPs uniquely detected by the ML ensemble

Functional enrichment analyses reinforced this inference: candidate genes showed significant overrepresentation of immune pathways, particularly those governing cytokine signalling and T-helper cell responses. Interleukin-1 receptor activity exhibited the strongest enrichment, followed by Th1-associated cytokine production and IL-18-mediated signalling cascades. The coordinated enrichment of IL-1 and IL-18 pathways underscores the centrality of pro-inflammatory cytokine responses in modulating MAP susceptibility. More broadly, the enrichment of cytokine and immune receptor-related pathways suggests that host genetic variation shaping receptor-mediated immune recognition plays a key role in determining differential vulnerability to MAP infection (Fig. 10a, b).

Discussion

Model performances and implications for the genetic architecture of MAP resistance

The consistent performance hierarchy observed across nine algorithmically distinct classifiers (Table 3) provides

Fig. 10 GO-Term and Pathway Enrichment Mapping of Immune Signalling Processes

direct insight into the genetic architecture governing MAP susceptibility rather than merely reflecting methodological preference. The systematic and reproducible underperformance of penalised linear models relative to tree-based and probabilistic classifiers—manifest not in discrimination alone but across calibration,

generalisation stability, and confusion-matrix balance—constitutes evidence that the host genotype–phenotype mapping for paratuberculosis resistance is not fully captured by purely additive allelic effects. Critically, however, the fact that linear models still achieve strong absolute performance ($\text{AUC} \geq 0.982$) indicates that a

substantial additive component does exist; it is the residual performance gap—most pronounced in MCC and recall—that exposes the additional contribution of non-additive genetic effects, including epistasis and possible dominance interactions among loci. This architectural inference is independently supported by cross-method benchmarking: the ML ensemble shared 24 of its top 50 SNPs with the additive mixed linear model and 31 with McNemar's test, while uniquely identifying 10 loci captured only by interaction-sensitive algorithms (Fig. 8), indicating predominantly combinatorial rather than marginal phenotypic effects. The near-perfect feature-importance concordance among tree-based ensembles and Naive Bayes ($r=0.993$ – 0.999), contrasted with their marked divergence from linear architectures ($r=0.468$ – 0.671), further implies that the non-additive signal is not model-specific noise but a reproducible structure in the data that interaction-capable algorithms converge upon independently. From a breeding perspective, this layered architecture—where additive polygenic effects coexist with epistatic modifiers—argues against reliance on any single modelling paradigm for genomic prediction of MAP resistance and instead supports the ensemble philosophy adopted here, in which complementary inductive biases are deliberately combined to interrogate the full spectrum of genetic effects shaping host–pathogen interaction.

Inter-model concordance topology and implications for consensus-based marker discovery

The overlap coefficient heatmap (Fig. 8) reveals a stratified concordance topology shaped by three interacting factors: optimization paradigm, regularization geometry, and sensitivity to interaction architectures. Rather than a clean block-diagonal partition, the matrix exposes a gradient of inter-model agreement with hierarchical but permeable boundaries among algorithmic families.

Penalized linear models (Logistic Regression L2 and Elastic Net) exhibit near-maximal internal concordance (0.840), consistent with their shared convex optimization framework and similar shrinkage behavior under L2-dominant regularization. Bagging-based ensembles (Random Forest and Extra Trees) form a second high-agreement pair (0.720), reflecting their common variance-reduction strategy via bootstrap aggregation. The boosting subfamily shows moderate but internally heterogeneous cohesion: LightGBM–Gradient Boosting and XGBoost–LightGBM each reach 0.500, whereas XGBoost–Gradient Boosting falls to 0.400, indicating that implementation-level differences produce non-trivial divergence even among sequentially trained residual-fitting models.

A notable finding is the asymmetric permeability of cross-family boundaries. Bagging ensembles share

0.400–0.440 of their top markers with the penalized linear models—values approaching several within-boosting comparisons—suggesting that bagging partially recovers additive marginal-effect signals that linear classifiers also detect. By contrast, Gradient Boosting shares only 0.080–0.140 with the same linear methods, the lowest cross-family overlap in the entire matrix, indicating that its sequential residual-fitting strategy prioritizes interaction-dominated features that linear frameworks are structurally unable to capture.

XGBoost occupies a distinctive bridging position within this landscape. Although Extra Trees achieves a marginally higher mean overlap (0.385 versus 0.375), this is driven primarily by its strong bilateral connection with Random Forest. XGBoost instead exhibits the most evenly distributed concordance profile: six of its eight pairwise overlaps equal or exceed 0.340, spanning both tree-based and linear families, likely reflecting its regularized objective function combining second-order gradient optimization with L1/L2 penalties. SVM Linear and Naive Bayes form a fourth category of relatively isolated classifiers (ranges: 0.160–0.300 and 0.160–0.320, respectively), whose low overall concordance does not diminish their consensus value—markers reaching their top-ranked lists despite restrictive model assumptions carry additional evidence of marginal discriminative power.

From a systems-genomic perspective, inter-model discordance represents complementary projections onto the genotype–phenotype manifold rather than analytical instability. A marker endorsed by both a bagging ensemble and a penalized regression model has survived feature selection under orthogonal statistical assumptions, acquiring cross-architecture robustness that no single-model analysis can confer. Conversely, markers uniquely prioritized by interaction-sensitive ensembles may represent higher-order epistatic structures invisible to linear estimators, warranting retention as candidates for functional validation. These findings advocate for consensus-weighted discovery frameworks in livestock genomics, where incorporating overlap topology into candidate prioritization may enhance biological signal stability—a strategy of particular value under moderate sample size regimes where independent replication cohorts are rarely available.

Immunogenetic architecture underlying innate and adaptive immune regulation

Given that the majority of identified SNPs are inter-genic, their influence on the highlighted immune genes is likely mediated through regulatory mechanisms or linkage disequilibrium rather than direct coding alterations. Therefore, these genes represent putative candidates requiring functional validation. Nevertheless, the

biological plausibility of these proximity-based associations is strengthened by the coherent functional landscape they delineate: a diverse array of immune-regulatory genes orchestrates host defense, shaping antiviral resistance, inflammatory homeostasis, antigen processing, and immunopathology. The genes examined here converge on several core immunological modules—including interferon-stimulated antiviral programs, cytokine receptor signaling, immune checkpoint control, phagosome and autophagy pathways, glycan-mediated T-cell regulation, and NF- κ B-dependent inflammation—revealing a multilayered network governing both innate and adaptive immunity. In this context, we further highlight the subset of genes identified through our Machine Learning-based GWAS annotation pipeline that are already known to participate in immune system regulation, providing an integrated synthesis of ML-driven discovery with established immunobiological function.

Interferon-stimulated genes and antiviral innate immunity

Interferon-inducible loci such as IFI27L2, IFI44, and IFI44L encode antiviral effectors that shape cell-intrinsic immunity. IFI27L2 localizes to mitochondria where it promotes apoptosis and restricts replication of neurotropic viruses including West Nile virus, operating as a cell type-specific antiviral determinant [37, 38]. IFI44 and IFI44L suppress IRF3 and NF- κ B signaling by FKBP5-dependent inhibition of IKK kinases, functioning as negative feedback regulators that fine-tune type I/III IFN responses [39, 40]. Their strong induction across infection contexts—including influenza, RSV, HIV and hepatitis viruses—illustrates their conserved role in antiviral defense [41]. In bacterial immunity, IFI44L constrains early *Mycobacterium tuberculosis* growth, while epigenetic dysregulation of IFI44L and elevated IFI44 expression contributes to autoimmunity [42]. Collectively, these ISGs integrate pathogen sensing with inflammatory resolution, balancing antiviral potency and immunopathology.

Cytokine receptors governing innate–adaptive crosstalk

The IL18R1–IL18RAP–IL1R1–IL1RL2 receptor cluster constitutes a central hub coordinating early inflammatory signaling. IL1R1 drives neutrophil recruitment and acute inflammation through MyD88-dependent NF- κ B activation [43]. The IL-18R1/IL-18RAP complex synergizes with IL-12 to elicit robust IFN- γ production by NK and Th1 cells, promoting type-1 immunity against intracellular pathogens [44]. Genetic evidence links IL18RAP variants to Crohn's disease, ulcerative colitis, and leprosy, where alleles reduce receptor surface expression and weaken NF- κ B/MAPK responses in monocyte-derived macrophages [45, 46]. IL1RL2 (IL-36R) activates epithelial-driven inflammation, particularly in fungal infection

and psoriasis [47]. Together, this receptor cluster modulates the magnitude and quality of innate recruitment, Th1/Th17 polarization, epithelial immunity, and chronic inflammatory susceptibility.

Immune checkpoint and immune-evasion regulators

Multiple genes in the dataset directly influence immune escape, T-cell suppression, and immune checkpoint dynamics. IMP3 (IGF2BP3) represses stress-induced NKG2D ligands ULBP2 and MICB, thereby dampening NK-cell surveillance and facilitating tumor immune evasion [48]. Additional IMP family members enhance immune checkpoint expression and limit interferon signaling, contributing to immunotherapy resistance [49]. HNRNPH1, a key RNA-binding protein, stabilizes NEAT1v2 to promote IL-8 transcription and controls the translation of JAK2 and PD-L1/PD-L2, integrating innate inflammation with adaptive immune suppression [50, 51]. Its transcriptional repression by AhR upregulates PD-L1 and IDO1, further strengthening immunosuppressive programs [52]. Additionally, ADGRL4, enriched in endothelial cells, fosters an immunosuppressive tumor microenvironment through M2-like macrophage polarization and PD-L1 upregulation, while impairing T-cell infiltration [53, 54]. These pathways collectively highlight the tight coupling between stromal signaling, NK/T-cell activation thresholds, and immune evasion.

NF- κ B pathway regulators and inflammasome-linked immunity

Innate immunity relies heavily on NF- κ B-mediated transcriptional activation. OTUD1, a deubiquitinase, acts as a central negative regulator by targeting MAVS, TRAF3/6, and IRF3 for inactivation, thereby constraining type I IFN production. OTUD1 deficiency markedly enhances antiviral and antifungal immunity [55–57]. PPP4R4, through PP4C complexes, also suppresses TBK1 phosphorylation to downregulate antiviral signaling, reflecting an evolutionarily conserved mechanism for preventing excessive inflammation [58]. TRAPPC9 (NIBP) enhances NF- κ B activation downstream of TLR signaling and is associated with heightened inflammatory cytokine production in macrophage-driven infectious mastitis [59, 60]. S100B, functioning as a danger-associated molecular pattern (DAMP), triggers MyD88/TRIF-dependent NF- κ B activation and amplifies cytokine secretion, integrating metabolic stress with pathogen-driven inflammation [61]. These networked regulators calibrate the threshold between protective inflammation and harmful immunopathology.

Together these genes define a multi-tiered immunogenetic framework integrating antiviral interferon responses, cytokine receptor signaling, immune checkpoint regulation, vesicular antimicrobial pathways, and

glycan-mediated T-cell control. Their coordinated activity illustrates how genetic variation shapes susceptibility to infection, chronic inflammation, immune evasion, and therapeutic responsiveness—providing a scalable foundation for precision immunology and host-directed interventions.

Immunological signalling networks associated with MAP susceptibility

Pathway analysis provides a mechanistic perspective on how SNP-level associations converge on coordinated biological processes, enabling the identification of signalling networks that may underlie differential susceptibility to infectious diseases. By integrating multi-model GWAS outputs with functional annotation, this analysis highlights immune pathways whose perturbation can alter host defence, cytokine signalling dynamics, and the interplay between innate and adaptive immunity.

Interleukin-1 receptor (IL-1R) signalling constitutes one of the core pathways of innate immune activation and plays a central role in host defence against infectious diseases. IL-1R family members—particularly IL-1R1 and IL-1R2—mediate the actions of the pro-inflammatory cytokines IL-1 α and IL-1 β , triggering neutrophil recruitment, fever induction, and acute-phase protein synthesis [62]. Through MyD88-dependent signalling, IL-1R activation drives NF- κ B and MAPK pathways, thereby enhancing antimicrobial peptide production and phagocyte function [63]. Impaired IL-1R activity increases susceptibility to bacterial, viral, and fungal pathogens and delays pathogen clearance [64]. Beyond innate immunity, IL-1R signalling provides essential cues for adaptive immune activation by modulating T-cell differentiation and antibody responses [65].

Regulation of Th1 cytokine production represents a crucial axis of cellular immunity and is predominantly orchestrated through the reciprocal interplay between IL-12 and interferon- γ (IFN- γ). IL-12 derived from antigen-presenting cells activates STAT4, initiating the differentiation of naïve CD4+ T cells toward a Th1 phenotype and inducing the expression of the transcription factor T-bet. This IL-12–STAT4 signalling cascade forms a critical bridge between innate and adaptive immunity, as pathogen-derived stimuli stimulate IL-12 secretion, which in turn promotes robust IFN- γ production by natural killer and T cells [66].

The IL-18–mediated signalling pathway is another fundamental regulator of both innate and adaptive immune responses. IL-18 binds to a heterodimeric receptor composed of IL-18R α and IL-18R β , initiating MyD88-dependent signalling through its TIR domain [67]. As a member of the IL-1 cytokine family, IL-18 relays danger signals to immune cells that cannot directly recognise microbial antigens, thereby strengthening innate

immune activation and linking it to downstream adaptive responses [68]. During infectious disease, IL-18 plays a particularly pronounced role. For example, during influenza A virus infection, NLRP3 inflammasome activation converts pro-IL-18 into its mature form, promoting effective adaptive immune responses [69].

IL-18 functions synergistically with IL-12 to activate natural killer cells and protect the host against infections and malignancies. Mouse models lacking IL-18 show impaired NK-cell activity and heightened infection susceptibility. Clearance of intracellular bacteria, fungi, protozoa, and viruses requires host-derived interferon- γ , for which IL-18 is indispensable. In *Mycobacterium avium* infection, IL-18 mediates protective immunity by inducing IFN- γ , while in *Leishmania major* infection, co-administration of IL-12 and IL-18 confers resistance to reinfection. IL-18 also enhances cytotoxic CD8+ T-cell activation and supports antiviral defence, as demonstrated by impaired viral clearance in IL-18-deficient mice. The proteolytic conversion of pro-IL-18 to its active form by caspase-1 following inflammasome activation amplifies innate immune responses to microbial antigens and danger signals, thereby providing a mechanistic link between early immune activation and subsequent adaptive immunity [68].

The regulation of Th1-type immune responses forms a central determinant of host protection, as the balance between Th1 and Th2 differentiation dictates susceptibility to bacterial, parasitic, and viral pathogens. IL-12 directs Th1 polarization, whereas IL-4 promotes Th2 commitment, establishing a cytokine environment that determines adaptive immune trajectories. During early responses to intracellular pathogens, macrophage-derived IL-12 acts as the initiating cue by stimulating natural killer cells to produce IFN- γ . This initial IFN- γ burst enhances macrophage activation and induces further IL-12 secretion, forming a self-reinforcing loop that stabilises Th1 programming. At the transcriptional level, IL-12 signalling activates the STAT family—especially STAT4—which serves as a principal regulator of Th1 lineage commitment. Disruption of this axis severely compromises Th1 immunity, highlighting its non-redundant role in antiviral and antibacterial defence [70].

Cytokine receptor activity, defined as the binding of cytokines to their specific cell-surface receptors and the initiation of downstream signal transduction, is essential for regulating innate immunity through the JAK-STAT pathway [71]. Upon pathogen recognition by pattern-recognition receptors, inflammatory cytokines such as IL-1, IL-6, TNF- α , and IFN- γ bind their cognate receptors to activate JAK proteins, trigger STAT phosphorylation, and induce transcription of antimicrobial effector genes [72]. Interleukin receptors are particularly critical in bacterial infection; for example, IL-27 receptor signalling drives

excessive immunosuppression during neonatal Gram-negative sepsis [73].

Immune receptors provide the molecular foundation for pathogen detection and immune activation. Key receptor families—including Toll-like receptors (TLRs) and nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs)—identify pathogen-associated and damage-associated molecular patterns [74, 75]. Their activation initiates signalling cascades that guide both innate and adaptive immune responses, ensuring coordinated host defence against invading microorganisms [76].

Conclusion

This study presents the largest caprine paratuberculosis genomic survey conducted in Türkiye, encompassing 3,372 goats from seven native breeds across 11 provinces and four geographic regions. By applying mutual information-based feature preselection to reduce 44,375 quality-controlled SNPs to an informative subset of 500 markers, and subsequently deploying nine complementary machine-learning algorithms within a fully nested cross-validation framework (5 folds $\times$ 5 seeds), we established a methodologically rigorous pipeline that converged on a narrow test-set AUC range of 0.982–0.992 across all classifiers. The ensemble importance framework—integrating weighted averaging, Borda count, and Kemeny–Young aggregation with permutation-based FDR control—resolved 31 SNPs on 16 chromosomes that were consistently associated with MAP serostatus, demonstrating that the identified signal is algorithm-independent and robust to stochastic variation.

The 31 candidate loci map predominantly to intergenic regions (27 of 31) yet cluster near genes governing core immune processes: interferon-stimulated antiviral defence (IFI44, IFI44L, IFI27L2), interleukin receptor-mediated innate–adaptive crosstalk (IL1R1, IL1RL2, IL18R1, IL18RAP), NF- κ B-dependent inflammatory regulation (OTUD1, TRAPPC9, S100B), and the chromosome 21 serpin cluster implicated in inflammation and coagulation homeostasis. Functional enrichment confirmed significant overrepresentation of IL-1 receptor activity, Th1 cytokine production, and IL-18 signalling cascades, delineating a biologically coherent immune landscape. The systematic performance advantage of nonlinear over linear classifiers—particularly in MCC and recall—indicates that MAP resistance harbours non-additive genetic components alongside its substantial additive architecture, an inference independently supported by the partial but significant overlap of the ML ensemble with both the mixed linear model (24 of 50 top SNPs shared) and the genome-wide McNemar test (31 of 50 shared; 15 common to all three methods).

These findings outline a practical foundation for marker-assisted selection aimed at enhancing MAP resilience in goat populations. The 31 validated SNPs, once confirmed in independent cohorts, could be incorporated into low-density genotyping panels for genomic evaluation, enabling breeders to select for reduced susceptibility without compromising production traits. By curtailing pathogen shedding at its animal-source origin, such genomic strategies would complement existing surveillance and management measures within a broader One Health framework, simultaneously benefiting livestock productivity, environmental biosecurity, and—given the reported associations between MAP and chronic inflammatory diseases in humans—public health.

Several limitations warrant consideration and define priorities for future research. First, the predominantly intergenic location of identified SNPs means that gene assignments are proximity-based (± 200 kb) and require functional validation through eQTL mapping, chromatin conformation capture, or CRISPR-based perturbation experiments. Second, although the inclusion of seven genetically and geographically diverse breeds—spanning four distinct regions of Türkiye—substantially strengthens the generalisability of the reported associations and reduces the likelihood that the identified signals are breed- or population-specific artefacts, replication in independent international cohorts raised under different management systems and climatic conditions remains necessary to confirm their broader translatability. Third, although the matched-pair design controlled for farm, breed, age, and sex effects, larger sample sizes would increase power to detect small-effect loci and to formally model gene–environment interactions that may modulate MAP susceptibility across diverse production settings. Finally, longitudinal studies tracking seroconversion dynamics alongside genomic profiles would clarify whether the identified loci influence the timing and magnitude of immune responses to MAP exposure, thereby refining both the biological interpretation and the breeding value estimation of these candidate markers. Addressing these research priorities within an integrated One Health framework—linking genomic selection in livestock with environmental surveillance of MAP shedding and epidemiological monitoring of potentially associated human inflammatory conditions—will be essential to translate the preliminary markers reported here into actionable tools that simultaneously safeguard animal productivity, reduce environmental pathogen burden, and mitigate zoonotic risk.

Acknowledgements

This project was supported by the Scientific and Technological Research Council of Türkiye (TÜBİTAK), and we extend our sincere gratitude to TÜBİTAK for their support. The corresponding author also expresses profound gratitude to Gazi Mustafa Kemal ATATÜRK, the founding leader of modern Türkiye.

Authors' contributions

Y.Y. conceptualized and designed the study, performed the GWAS analysis, and wrote the manuscript. Y.Y., R.A., M.K., Ö.G., and K.I. conducted the laboratory work. S.Y. organized the field work. Y.Y., A.E., D.C., Y.E.K., S.S.S., and M.B. conducted the field work and data collection.

Data availability

The data used in this study have been deposited in the figshare.com database under <https://doi.org/10.6084/m9.figshare.30845045>.

Declarations

Ethics approval and consent to participate

This study was conducted in accordance with the guidelines of the Local Ethics Committee for Animal Experiments and with an experimental protocol approved by the "Ethics Committee for the Use of Animals in Research and Experimentation" at the Sheep Breeding and Research Institute, Türkiye (Approval No: 066/14.02.2023). Informed consent was obtained from the Ministry of Agriculture and Forestry, Siirt Provincial Directorate of Agriculture (Approval No: E-64380313-325.01-8848896/08.02.2023) prior to the study. The authors also complied with the ARRIVE guidelines.

Consent for publication

Not applicable.

Competing interests

The authors declare no competing interests.
